This is an open book and notes exam. There are 6 parts and 8 pages. Make sure that you have them all before you begin. The duration is 1 hour.

PART 1 (10 points)

The program

```c
int main( int argc, char *argv[], char *env[] )
{
    ... 
}
```

is compiled and linked with “gcc main.c” and run with

```
> a.out main.c -nodebug
```

Assume that the environment (as listed by “printenv”) is

```
ED=joe
UNAME=sdc
```

Complete the “box and arrow” diagram that shows how the command line arguments and environment are made accessible to `main()` under Solaris UNIX. Show all relevant null pointers.

```
argc

argv

env
```
PART 2 (15 points)
An array of function pointers can be used to bind "action functions" to "events" so that which action function is called when a particular event occurs can vary during runtime.

Assume that a legal event number is an integer in the range 0 to MAX_EVENT.

Assume that an action function should be called with the event number as its one argument and it should return nothing. One action function is defined by

```c
void default_Action( int event )
{ /* Do nothing */ }
```

The type "pointer to action function" is declared by

```c
typedef void (* pAction_type )( int );
```

Assume that the current bindings of events to action functions is stored in the array of function pointers

```c
extern pAction_type pActions[MAX_EVENT];
```

1. Write the function below that will take an event number and do the following:

(a) Check if the event number is legal. If it is not, call bad_event (declared below) with the event number as its one argument. Then call exit(1).

```c
extern void bad_event( int event );
```

(b) Call the action function whose pointer has been stored in the position of pActions given by the event number. Then return.

```c
void dispatch_event( int event )
{
```

```c
}
```

This problem is continued on the next page
2. Write the function below that will replace the old binding for an event with a new binding.
   It should:

   (a) Check for event legality (as dispatch_event did.)

   (b) Replace the old action function pointer for event number event with the given new one.

   (c) If the pointer to the new action function is NULL then put in default_Action as the new
       binding.

   (d) Function bind should return the old pointer value that used to be stored in the indicated
       position of the array pActions. (This way, the caller can save that pointer so it may be
       restored by a later call to bind.)

   pAction_type bind( int event, pAction_type pNewAction )
   {
   }
PART 3 (15 points) Consider the following Makefile:
(What cat and echo do is described in the comments.)

SRCS = G H K
RESULTS = A B C D E F

all : A B C D
    echo Hello #Print Hello when run.

A : E
    cat E > A #Copy file E to file A.

B : F E
    cat F E > B #Concatenate files F, E, write result to B.

C : F
    cat F > C

E : G H
    cat G H > E

F : H K
    cat H K > F

D :
    lpr $(SRCS)

clean :
    rm -f $(RESULTS)

1. Locate the first rule in this Makefile. Circle and label (a) the target, (b) the dependencies, and (c) the command of this rule.
   This problem is continued on the next page
2. The following (obtained by `ls -l`) shows all the files in the working directory together with their modification times.

<table>
<thead>
<tr>
<th>Mode</th>

<td>makefile</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Based on this information, write here exactly what is printed to the terminal when the command `make all` is given:

PART 4 (20 points)
Show how the binary form of these dlx402 instructions is decoded. Write after each instruction a precise description of the changes of register and/or memory values that it causes. Assume the instructions are loaded beginning at address 0 and are executed sequentially, and the memory and registers are initialized as in project 3.

0x2003ffff

0x00632821

0xac630011
PART 5 (20 points) This problem is to construct the state and action table for a line scanner that processes lines of a simplified generic assembly language. CAUTION: The language is different from the language in your project. Write your answer in pencil (so you can erase) on the next page.

Don’t worry about illegal characters. The characters have been classified into 4 disjoint classes: R, WS, COLON and NL.

Assume the input line will end with NL.

Every label, operator and operand is one or more R (“ordinary”) characters.

A legal input line is either null (zero or more WS characters, of course terminated by NL), or is described by the following sequence:

1. An optional label that must begin (if present) at the first column. If there is no label the first character must be WS. The label is delimited by a COLON at the end.

2. A mandatory operator. The operator must begin after the first column or after the COLON of a label. There are zero or more WS characters between the first column or the COLON and the beginning of the operator.

3. Zero or more operands. They are separated from the operator and from each other by one or more WS characters. There might (or might not) be WS characters after the last operand (before the NL).

Actions:

1. At the beginning of each label, operator and operand, mark_act should be called.

2. At the character after each label, operator and operand, label_act, operator_act, and operand_act should be called, respectively.

Ending:

1. If the line is “null”, the state machine should go to state “null” when the NL is processed.

2. For non-null, correct input, the ending state should be “done.”

3. As soon as the scanner detects a violation of the above rules, the state machine should go to state “error.”

It may help some of you to see an (extended) grammar for the language:

<table>
<thead>
<tr>
<th>line</th>
<th>null_line</th>
<th>ordinary_line</th>
</tr>
</thead>
<tbody>
<tr>
<td>null_line ::= null_line</td>
<td>null_line</td>
<td>ordinary_line</td>
</tr>
<tr>
<td>ordinary_line ::= (label:</td>
<td>ordinary_line ::= (label:</td>
<td>WS* operator (WS+ operand)*</td>
</tr>
<tr>
<td>label: add 96H B</td>
<td>abc: add 96H B</td>
<td>abc: add 96H</td>
</tr>
<tr>
<td>add PQR 0x45g</td>
<td>add PQR 0x45g</td>
<td>add PQR 0x45g</td>
</tr>
<tr>
<td>add</td>
<td>add</td>
<td>add</td>
</tr>
<tr>
<td>label: add</td>
<td>label: add</td>
<td>label: add</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>

    { NL, }},

transition bef_operand_row[] = {
    { WS, },
    { R, },
    { COLON, },
    { NL, }},

transition in_operand_row[] = {
    { WS, },
    { R, },
    { COLON, },
    { NL, }};
PART 6 (20 points)
(a.) Write a function that returns the first source operand for dlx402 instruction to be simulated. Remember that this operand is designated by bits 6-10 of the instruction. Remember also the special properties of register 0.

```c
unsigned long get_rs1( unsigned long instrucion, unsigned long regs[] )
{ /* Assume register i is implemented by regs[i] */
}
```

(b.) Write a function that writes back the result of an immediate (or memory load) dlx402 instruction into a register. Remember that the destination register for this type of instruction is designated by bits 11-15. Be sure your answer here is consistent with your answer above.

```c
void write_back_imm_type( unsigned int instruction,
                           unsigned long value,    /*value to write back*/
                           unsigned long regs[] )  /*simulated reg. array*/
{ /* Assume register i is implemented by regs[i] */
}
```
